## **Abstract**

Emissions of sulfur dioxide (SO<sub>2</sub>) from the US power sector decreased by 24% in 2009 relative to 2008. The logarithmic mean Divisia index (LMDI) approach was applied to isolate the factors responsible for this decrease. It is concluded that 15% of the decrease can be attributed to the drop in demand for electricity triggered by the economic recession, 28% to switching of fuel from coal to gas responding to the decrease in prices for the latter. The largest factor in the decrease, close to 57% resulted from an overall decline in emissions per unit of power generated from coal. This is attributed in part to selective idling of older, less efficient coal plants that generally do not incorporate technology for sulfur removal, in part to continued investments by the power sector in removal equipment in response to the requirements limiting emissions imposed by the US Environmental Protection Agency (US EPA). The paper argues further that imposition of a modest tax on emissions of carbon would have ancillary benefits in terms of emissions of SO<sub>2</sub>.

## **1. Introduction**

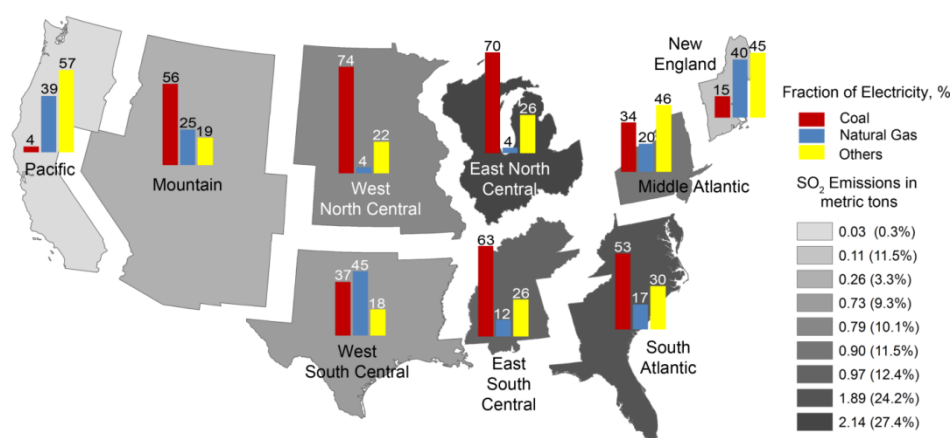

Overall generation of electricity in the US decreased by 4.1% between 2008 and 2009. Carbon emissions from the power sector, which accounts for approximately 40% of total US greenhouse gas emissions, declined over the same period by an even larger factor, by 8.76 % in 2009 relative to 2008. Part of this reduction was attributed to the recession that set in during late 2008 with an important additional contribution due to a price-induced shift in the generation of electricity from coal to gas. Lu et al (1), using an econometric model, concluded that the increase in the use of natural gas relative to coal was responsible for a 4.3% reduction in CO<sub>2</sub> emissions from the US power sector over and above the 4.1% reduction attributed to the recession.

We focus in this paper on the implications of the shift in the power mix and other factors for sulfur dioxide ( $\text{SO}_2$ ).  $\text{SO}_2$  is an important air pollutant responsible for production of sulfate aerosols impacting not only public health (2, 3), but also acid rain and potentially climate (4). Recent studies (5, 6) suggest that warming of the climate by increasing level of greenhouse gases has been significantly offset by cooling due to the direct and indirect impact of aerosols, with particular attention to the role of sulfur. Combustion of fossil fuels in the electric power sector represents the dominant anthropogenic source of  $\text{SO}_2$  emissions in the US. Emissions of  $\text{SO}_2$  in the US amounted to 10.4 million metric tons (MT) in 2008 with 66% associated with the generation of electricity using sulfur-containing fuels (mainly coal), 28% from varied industrial activities, with the balance from a combination of on-road and off-road transportation (4.6%) and other miscellaneous sources (1.4%) (7, 8). Emissions from the US power sector decreased by 24% in 2009 as compared to 2008, from 7.8 MT to 6.0 MT (9). The decrease was significantly greater than the corresponding drop either in total power production or in emissions of  $\text{CO}_2$ . We argue here that the primary factor responsible for the reduction in  $\text{SO}_2$  emissions in 2008 relative to 2009 involved a decrease in emissions of  $\text{SO}_2$  per unit of electricity produced (we refer to this as the  $\text{SO}_2$  emission intensity). Price induced switching from coal to gas also contributed, as did the decrease in total power production. As we shall indicate in what follows, the reduction in  $\text{SO}_2$  emissions occurred despite the fact that the sulfur content of coal consumed by the power sector was actually higher in 2009 than in 2008.

Our analysis makes use of the Logarithmic Mean Divisia Index (LMDI) approach as described in Section 2. Results are presented and discussed in Section 3. We propose to treat not only what took place on a national scale but also what developed regionally. For the latter purpose, we chose to focus on census regions, building on the earlier  $\text{CO}_2$  analysis (1). Implications for  $\text{SO}_2$  of a potential tax on emissions of carbon from the power sector are discussed in Section 4, with discussion included in

## 2. Methodology and Data

A number of factors is expected to contribute to changes in emissions of  $\text{SO}_2$  from the US power sector, specifically changes in electricity production, differences in fuel mix, in the sulfur content of fuels (mainly coal and oil), and in the efficiencies for removal of  $\text{SO}_2$ . The fuel mix for electricity generation varies to a significant extent across the US. The bar graphs in **Figure 1** illustrate the fractions of electricity that were generated using coal, natural gas and other fuels for different census regions in 2008 with grayscales indicating the strengths of related emissions of  $\text{SO}_2$ . As illustrated in **Figure 1**, coal is the dominant fuel employed for electricity generation in the West North Central, East North Central and East South Central regions. As a result,  $\text{SO}_2$  emissions are relatively high in these regions (10) . Other generating sources (including natural gas, hydro power, nuclear, oil and renewables) are more important for New England and for the contiguous Pacific region. Emissions of  $\text{SO}_2$  are much lower as a consequence in these regions. Alaska and Hawaii were excluded from the Pacific census region since generation of electricity from coal is negligible in these states.

**Figure 1** The composition of electricity generation for the nine US census regions in 2008. The grayscales for each region indicate the amounts of  $\text{SO}_2$  emissions from their power sectors for the same year.

As indicated by **Figure 1**, the magnitude of SO<sub>2</sub> emissions from the power sector is not determined solely by total power production or by the fraction of electricity generated using coal. The fraction of the total electricity produced using coal in the South Atlantic region is roughly the same as for the Mountain region. While the former generates less than twice as much as electricity as the latter, its emissions of SO<sub>2</sub> are more than seven times greater. Other factors, including the SO<sub>2</sub> emission intensity must also contribute to the distinction between emissions from the two regions. Similar considerations must be invoked to account for the fact that the Middle Atlantic region is responsible for 12% of total US power sector SO<sub>2</sub> emissions while producing 10% of the nation's electricity, despite the fact that only 34% of total power in this region is generated using coal.

Percent changes in electricity generation and SO<sub>2</sub> emissions for 2009 relative to 2008 for the nine census regions and for the entire contiguous US are summarized in Table 1. The changes in electricity generation by energy source varied significantly from region to region between 2008 and 2009 and their impacts on SO<sub>2</sub> emissions are similarly complex. The South Atlantic region, for example, was distinguished by an 18% decrease in generation of electricity using coal, a 21% increase in production from gas, with a 0.7% increase from other fuels, accompanied by the largest drop in SO<sub>2</sub> emissions (about 34%) as compared with other regions. In the contiguous Pacific region, electricity generated using coal, gas and other sources decreased by 16%, 3.8% and 1.7% respectively. Despite this, emissions of SO<sub>2</sub> increased by 5.4%. Although emissions of SO<sub>2</sub> and electricity generation from coal declined simultaneously between 2008 and 2009 in most regions except for the Contiguous Pacific, their change rates exhibited significant differences throughout the nine census regions.

**Table 1** Percentage changes of electricity generation and SO<sub>2</sub> emissions for the US power sectors in 2009 relative to 2008 for nine census regions and for the entire contiguous US. Data were derived from EIA-906, EIA-920, and EIA-923 (11) and US Energy Information Administration (12).

Regions	Electricity generation				SO <sub>2</sub> Emissions, %
	Coal,%	Natural Gas, %	Others,%	Total, %	
New England	-23	-0.4	-1.5	-4.3	-8.3
Middle Atlantic	-15	9.9	1.1	-2.8	-27
East North Central	-9.7	6.6	-5.7	-8.0	-22
West North Central	-3.3	-22	13	-0.6	-18
South Atlantic	-18	21	0.7	-5.8	-34
East South Central	-19	27	14	-5.3	-29
West South Central	-5.3	-0.7	5.5	-1.3	-5.8
Mountain	-5.9	-2.2	5.9	-2.7	-11
Contiguous Pacific	-16	-3.8	-1.7	-3.1	5.4
Contiguous US	-12	4.4	1.8	-4.1	-24

The primary purpose of this paper is to evaluate the relative importance of the different factors noted above in terms of their contributions to the observed changes in 2009 as compared to 2008. Emissions of SO<sub>2</sub> for a given region can be expressed as a product of the important relevant factors (total power generation, fraction produced by individual energy sources, and related fractional emissions of SO<sub>2</sub>) according to the KAYA identity (13):

$$S_j = \sum_i \left( E_j \cdot \frac{E_{ij}}{E_j} \cdot \frac{S_{ij}}{E_{ij}} \right) = \sum_i (E_j \cdot f_{ij} \cdot s_{ij}^E), \quad (1)$$

where  $S_j$  refers to the total emissions of SO<sub>2</sub> from the power sector in region j;  $E_j$  denotes the

corresponding production of electricity;  $f_{ij} \equiv \frac{E_{ij}}{E_j}$  represents the fraction of electricity generated from

individual sources  $i$  (coal, natural gas and others); and  $s_{ij}^E \equiv \frac{S_{ij}}{E_{ij}}$  defines the SO<sub>2</sub> emission intensities associated with different fuels (emissions per unit of electricity produced). Definitions of the different variables introduced here are summarized in Table 2.

The LMDI approach was adopted in order to separate the impacts of the different factors on the overall changes in emissions of SO<sub>2</sub>. This approach has been widely applied in analyses of energy demand and supply, carbon dioxide emissions, and efficiencies in energy related studies (14,15), and has proved to have advantages over other methodologies in terms of theoretical foundation, adaptability, ease of use, and ease in interpretation of results (14, 15, 16). With the logarithmic division approach, the unexplained residual terms may be allocated as contributions to the individual factors (17, 18, 19). If the residual terms are large, this could lead to unavoidable ambiguity in the assignment of influence to specific factors. Arguments supporting the validity of the approach in the present context, in which that the residual terms are relatively small, are presented in the supporting information (SI).

The changes in SO<sub>2</sub> emissions for each census region from 2008 to 2009 ( $\Delta S_j$ ) may be expressed in the additive form of the LMDI decomposition analysis (14) as a sum of impacts from the individual influential factors as follows:

$$\begin{aligned}\Delta S_j &= \Delta S_j^E + \Delta S_j^f + \Delta S_j^{s^E} \\ &= \sum_i \frac{\log(E_j^t) - \log(E_j^0)}{\log(S_{ij}^t) - \log(S_{ij}^0)} (S_{ij}^t - S_{ij}^0) + \sum_i \frac{\log(f_{ij}^t) - \log(f_{ij}^0)}{\log(S_{ij}^t) - \log(S_{ij}^0)} (S_{ij}^t - S_{ij}^0) + \sum_i \frac{\log(s_{ij}^{E^t}) - \log(s_{ij}^{E^0})}{\log(S_{ij}^t) - \log(S_{ij}^0)} (S_{ij}^t - S_{ij}^0)\end{aligned}\quad (2)$$

Here superscripts 0 and t refer to the beginning and ending years of interest, 2008 and 2009 for the present analysis.

**Table 2** Definitions of variables for the LDMI decomposition analysis

Variable	Definition
$i$	Index of fuels, $i = 1, 2, 3$ for coal, natural gas and other respectively
$j$	Index of US census regions, $j = 1 - 9$

$S_j$	Total SO <sub>2</sub> emissions in $j^{th}$ census region
$E_j$	Total electricity generation in $j^{th}$ census region
$S_{ij}$	SO <sub>2</sub> emissions from electricity generation using $i^{th}$ fuel in $j^{th}$ census region
$f_{ij}$	Share of electricity generation using of $i^{th}$ fuel in $j^{th}$ census region
$s_{ij}^E$	Emissions per kWh of electricity generated using $i^{th}$ fuel in $j^{th}$ census region
$s_j^{E_c}$	Emissions per kWh of electricity generated using coal in $j^{th}$ census region
$S_j^{E_c}$	SO <sub>2</sub> emissions from electricity generation using coal in $j^{th}$ census region
$E_{cj}$	Electricity generated from coal in $j^{th}$ census region
$s_j^c$	Average sulfur content of coal used for electricity generation in $j^{th}$ census region
$C_j^m$	Mass of coal consumed for electricity generation in $j^{th}$ census region
$Sr_j$	Average sulfur retention ratio of ash in $j^{th}$ census region
$\eta_j$	Average removal efficiency for SO <sub>2</sub> in $j^{th}$ census region
$Hc_j$	Average heat content of coal used for electricity generation in $j^{th}$ census region
$Hr_j$	Average heat rate of coal power plants in $j^{th}$ census region

Results from the decomposition process, discussed in Section 3, suggest that changes in SO<sub>2</sub> emission intensity for coal-fired systems are primarily responsible for the observed reductions in total emissions. To explore this further, we conducted a second level of analysis decomposing the emission intensity factor into a number of its relevant components. The SO<sub>2</sub> emission intensity for coal power plants in region  $j$  is defined in this case in terms of a number of related component factors including the efficiencies for removal of SO<sub>2</sub> by installed sulfur control systems ( $\eta_j$ ), average heat rates for generation of electricity ( $Hr_j$ ), and average sulfur contents ( $s_j^c$ ) and heat contents ( $Hc_j$ ) for coal consumed, in addition to the retention ratio for the sulfur deposited in bottom ash ( $Sr_j$ ). The decomposition process for the emission intensity ( $s_j^{E_c}$ ) is represented then as:

$$s_j^{E_c} = \frac{S_j^{E_c}}{E_{cj}} = \frac{s_j^c \cdot C_j^m \cdot (1 - Sr_j) \cdot (1 - \eta_j)^2}{C_j^m \cdot Hc_j / Hr_j} = s_j^c \cdot \frac{1}{Hc_j} \cdot Hr_j \cdot (1 - Sr_j) \cdot (1 - \eta_j)^2, \quad (3)$$

where  $C_j^m$  refers to the total mass of coal consumed in the region. For ease of reference, definitions for all of the variables incorporated in equations (1) - (3) are summarized in Table 2. Contributions due to the heat content of coal, the sulfur retention ratio of ash and the SO<sub>2</sub> removal efficiency are represented indirectly by the terms  $1/Hc_j$ ,  $(1 - Sr_j)$ , and  $(1 - \eta_j)$ . The factor of 2 in the formula reflects the ratio of the molar mass of SO<sub>2</sub> to that of sulfur in elementary form. Changes in the SO<sub>2</sub> emission intensity from 2008 to 2009 can be represented then using the additive form of the LMDI analysis using an approach similar to that adopted in the first-level analysis:

$$\Delta s_j^{E_c} = [\Delta s_j^{E_c}]^c + [\Delta s_j^{E_c}]^{Hc} + [\Delta s_j^{E_c}]^{Ir} + [\Delta s_j^{E_c}]^{Sr} + [\Delta s_j^{E_c}]^{\eta}$$

$$= \sum_{k=1}^5 \frac{\log(a_k^t) - \log(a_k^0)}{\log(s_j^{E_c t}) - \log(s_j^{E_c 0})} (s_j^{E_c t} - s_j^{E_c 0}) \quad (4)$$

As before, the superscripts  $t$  and  $0$  distinguish between variables referring to either 2009 ( $t$ ) or 2008 ( $0$ ). The term  $a_k$  in equation (4) refers to the  $k^{th}$  factor ( $k=1 - 5$ ) in equation (3).

The data used in the analysis were derived from publically accessible reports prepared by the U.S. Energy Information Administration (US EIA) and the U.S. Environmental Protection Agency (US EPA). Results for electricity generation in individual census regions and for the contiguous US were computed using monthly, state-by-state reports available on forms EIA-906, EIA-920, and EIA-923 (10). Corresponding data for emissions of SO<sub>2</sub> were obtained from forms EIA-767 and EIA-906 (11). The SO<sub>2</sub> emission intensity can be defined in terms of the ratio of SO<sub>2</sub> emissions from the power sector to the relevant source of electricity. Heat rates for power plants in addition to heat and sulfur contents of coal employed in each census region were computed using a weighted average of fuel consumption data summarized on forms EIA-906, EIA-920, and EIA-923. Sulfur retention ratios for ash were derived using emission factors for SO<sub>2</sub> appropriate for different types of boilers and coal, as summarized by the US EPA (20). Average removal efficiencies for SO<sub>2</sub> control systems were computed using the methodology described by Zhao et al. (21). Summaries of the data used in this study are presented in Tables S1 and S2 of the SI.

### 3. Results

As described in the previous section, we considered three factors in the first-level LMDI analysis: electricity generation ( $E_j$ ), fuel mix ( $f_{ij}$ ) and SO<sub>2</sub> emission intensity ( $s_{ij}^E$ ). The impacts by fuel source of the individual factors affecting SO<sub>2</sub> emissions for the entire US from 2008 to 2009, obtained as

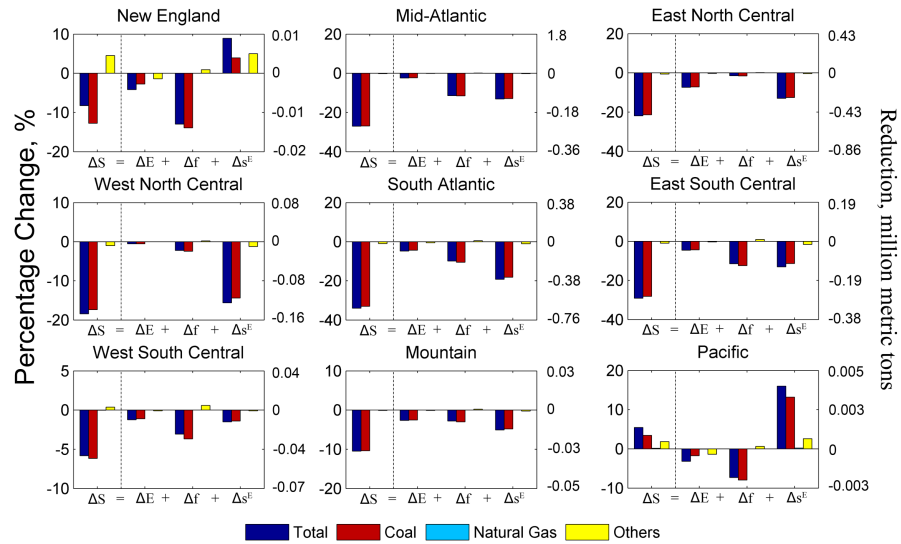

a result of this analysis, are summarized in Figure 2 (Results of analysis of 2009 to 2010 are illustrated in Figure S2 of the SI for the purpose of comparison). The results suggest that, on a national basis, changes in electricity generation, fuel mix, and SO<sub>2</sub> emission intensities were responsible for reductions of respectively 0.28 MT, 0.52 MT and 1.1 MT in SO<sub>2</sub> emissions between 2008 and 2009, accounting for respectively 15%, 28% and 57% of the total reduction. The economically driven decrease in electricity demand between 2008 and 2009 clearly contributed to this reduction. Price driven switching from sulfur-rich coal to sulfur-free gas made a further contribution (1, 22). The most important influence the analysis suggests, however, involved a significant decrease in the SO<sub>2</sub> emission intensity from the coal-fired power sector. The coal-fired power plants that were taken offline between 2008 and 2009, responding either to the decrease in demand for electricity or to the more competitive price of natural gas, typically involved some of the oldest, least efficient, plants. And for the most part, these plants had not been equipped with the technology to remove sulfur and other prescribed pollutants included in more modern facilities. The results in Figure 2 indicate that changes in deployment of the coal-fired component of the national power generating system were responsible for as much as 97.6% of the reduction in national emissions of SO<sub>2</sub> between 2008 and 2009.

**Figure 2** Reductions of SO<sub>2</sub> emissions and contributions due to changes in electricity generation ( $\Delta E$ ), fuel mix ( $\Delta f$ ), and SO<sub>2</sub> emission intensity ( $\Delta s^E$ ) expressed in terms of percentage for the

contiguous U.S. in 2009 relative to 2008. Values for natural gas are undetectable given the scales of the vertical axes.

Results obtained by applying the LMDI analysis to the nine census regions are summarized in Figure 3. Reductions in emissions were observed for all regions in 2009 with the exception of the Pacific. The decrease in emissions in the New England and West South Central regions is attributed primarily to changes in the fuel mix, a reduction in the quantity of electricity produced using coal in favor of an increase in production from other sources, mainly gas.  $\text{SO}_2$  emission intensities increased in the New England and Pacific regions. However, since emissions from these regions are relatively low, these changes had minimal impact on the national scale. For all other regions,  $\text{SO}_2$  emission intensities decreased, most notably in the West North Central and South Atlantic regions where overall  $\text{SO}_2$  emissions declined by 18% and 34% respectively. Results from the regional analysis are consistent with conclusions drawn from the national study summarized in Figure 2: reductions in  $\text{SO}_2$  emission intensities were primarily responsible for the nationwide decrease in emissions of  $\text{SO}_2$  in 2009.

**Figure 3** Reductions of  $\text{SO}_2$  emissions and contributions due to changes in electricity generation ( $\Delta E$ ), fuel mix ( $\Delta f$ ), and  $\text{SO}_2$  emission intensity ( $\Delta s^E$ ) expressed in terms of percentage and metric tons for the nine US census regions in 2009 relative to 2008. Values for natural gas are undetectable in all cases

given the scales of the vertical axes.

The second-level LDMI analysis described above was applied to a more detailed examination of the factors responsible for the decrease in the emission intensity of the coal-fired component of the national power system between 2008 and 2009. Results for the contiguous US are presented in Figure 4. The analysis suggests that more efficient removal of SO<sub>2</sub> as captured by the parameter  $\eta_j$  made the dominant contribution to the overall reduction in the SO<sub>2</sub> emission intensity. The sulfur content of the coal deployed in the power sector in 2009 was actually higher than that used in 2008, contributing thus to an increase in the composite emission intensity. Changes in heat contents of coal used ( $Hc_j$ ), retention rates for sulfur in ash ( $Sr_j$ ) and heat rates ( $Hr_j$ ) varied over at most a small range between 2008 and 2009. As indicated in Figure 4, these factors had a relatively minor influence on the net change in the emission intensity over this time period. The uncertainties of these factors may have a considerable impact on the contributions from the changes in SO<sub>2</sub> removal efficiencies (the dominant factor identified here) due to the connection defined by equation (3). A sensitivity analysis is included in the SI to address this issue.

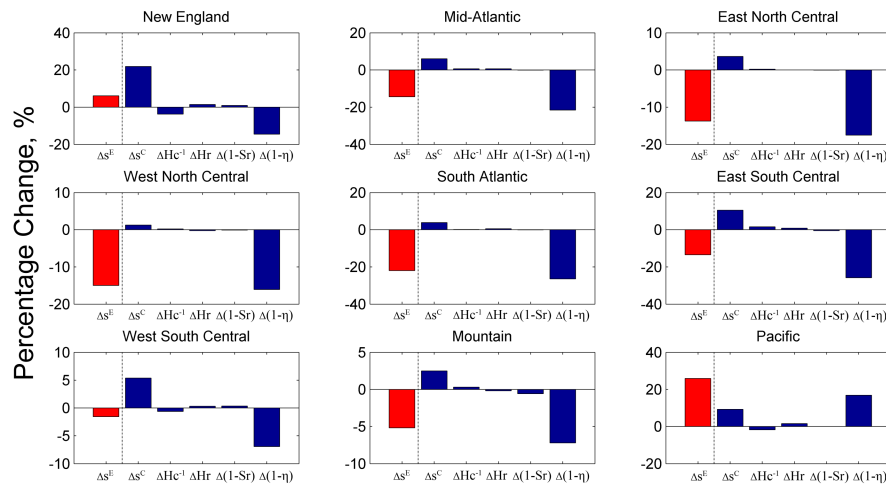

**Figure 4** Reductions of SO<sub>2</sub> emissions intensity of coal-electricity generation and contributions due to changes in sulfur contents ( $\Delta s^C$ ), heat contents ( $\Delta Hc$ ), heat rates of generation ( $\Delta Hr$ ), sulfur retention of ash ( $\Delta Sr$ ), and SO<sub>2</sub> removal efficiency ( $\Delta \eta$ ) for the contiguous U.S. in 2009 relative to

2008.

A combination of factors was responsible for the increase in the emission removal efficiency  $\eta_j$ . The number of generating systems (primarily coal) equipped with flue-gas desulfurization technology increased from 327 in 2008 to 384 in 2009 contributing to an increase from 140 GW to 168 GW in the capacity of systems equipped to remove sulfur. A further influence involved an important decrease in the fraction of electricity generated using older coal-fired plants in 2009 as compared to 2008 as indicated in Figure S4 of SI. The efficiency for generation of electricity using some of the older coal-fired power plants ranges as low as 20%. Operational costs are also typically higher for the older as compared to for more modern plants. As a consequence, the oldest coal plants fall typically on the low end of the merit order scale (1, 23). As prices for natural gas decreased relative to coal in 2009 relative to 2008, and as demand for electricity decreased due to the economic recession, many of the older coal plants, which generally were not equipped to remove sulfur, were either idled or displaced in favor of more cost effective generation using either modern coal plants or by some of the most efficient gas fired systems (1, 24).

The results in Figure 4 indicate that the sulfur content of coal consumed in 2009 was marginally higher than that used in 2008, contributing to an increase in the net intensity emission factor. On a national basis, the sulfur content of the coal consumed in 2009 was 3.2% higher than in 2008 while the heat content decreased by 1% (21). The decrease in heat content reflected a modest switch in percentage from higher-energy bituminous coal to lower-energy sub-bituminous fuel. The overall decrease in electricity consumption, in combination with an overall decrease in production using coal, may have reduced the pressure on utilities to limit emissions of sulfur. This could account for the larger fraction of higher sulfur, and potentially cheaper bituminous coal consumed in 2009 as compared to 2008 as indicated in Figure S5 of SI.

Results from the application of the second-level LMDI analysis to the individual census regions are summarized in **Figure 5**. For most regions, the relative contributions of the different factors are similar to those inferred for the nation as a whole. The increase in the removal efficiency was greatest as expected in the regions where most of the older coal fired plants were located, notably in the East North Central, East South Central, Middle Atlantic and South Atlantic regions (26). Emissions actually increased in the New England and Pacific regions due primarily in the former case to the use of higher sulfur coal with a further contribution in the latter case associated with a decrease in the removal efficiency.

**Figure 5** Changes of SO<sub>2</sub> emissions intensity of coal-electricity generation and contributions due to changes in sulfur contents ( $\Delta s^C$ ), heat contents ( $\Delta Hc^C$ ), heat rates of generation ( $\Delta Hr$ ), sulfur retention of ash ( $\Delta Sr$ ), and SO<sub>2</sub> removal efficiency ( $\Delta \eta$ ) for the nine US census regions in 2009 relative to 2008.

#### 4. Immediate Co-benefits of a Carbon Tax

The potential impact of a tax on carbon emissions imposed on the power sector was discussed by Lu et al (1). A tax on carbon would have an affect similar to that associated with a reduction in the price of natural gas relative to coal, responding to the fact that, per unit of electricity produced,

emissions of carbon from consumption of gas are only about half of those from coal. Lu et al (1) argued that a modest price on carbon, as low as \$5 a ton, could result in a significant additional reduction in CO<sub>2</sub> emissions. We discuss here the implications of a carbon tax for emissions of sulfur. As in the earlier study, our focus is on the immediate impacts of such a tax. That is to say, we assume that the demand for electricity remains the same and that the response of the generating system to a change in the gas – coal price differential is the same as that simulated using the econometric model developed by Lu et al (1).

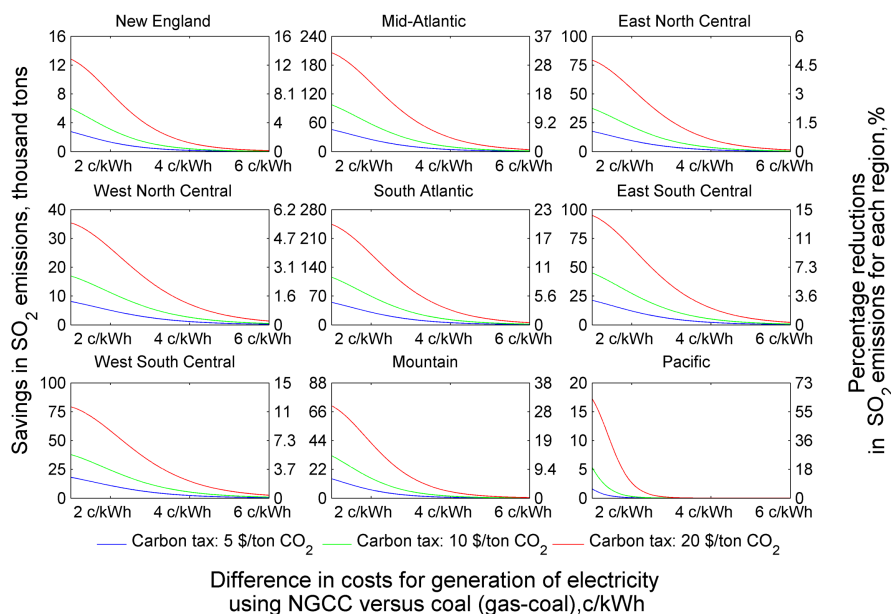

Regional results from the SO<sub>2</sub> analysis are presented in Figure 6. As expected, the additional savings in SO<sub>2</sub> emissions are greatest when the difference between gas and coal prices is at a minimum. As indicated in the figure, a tax of \$10 per ton of CO<sub>2</sub> imposed for example in the East South Central region would result in an additional reduction in SO<sub>2</sub> emissions of 27,000 tons (3.9% of total regional emissions) under conditions where the gas-coal cost differential (i.e., the annual cost of gas-fired minus coal-fired electricity) was at a level of 2 cents/kWh. The reduction would be negligibly small if the cost difference for generation of electricity using gas versus coal were to exceed 6 cents/kWh.

In practice, prices for both gas and coal vary across the country. Adopting reported regional prices for gas and coal in 2009 (11), the results in Figure 6 can be used to calculate the additional savings in SO<sub>2</sub> emissions that could have been realized for different levels of a hypothetical tax on carbon. The analysis implies that a tax of \$10 per ton of CO<sub>2</sub> (which would add on average 0.57 cents/kWh to the price of electricity) would have resulted in a further reduction of 362,000 tons of SO<sub>2</sub> on a national scale in 2009. Gas prices are currently much lower than they were in 2009, approximately \$2.5 per MMBTU in the first quarter of 2012 as compared to \$4.9 per MMBTU in 2009 (24). It follows that had prices of gas in 2009 been as low as they are today, the additional savings in emissions of SO<sub>2</sub> relative to 2008 projected to have arisen as a result of a tax on carbon of \$10 per ton CO<sub>2</sub> could have been realized at

even lower levels of this tax.

In estimating the change in SO<sub>2</sub> emissions that would have resulted from a carbon tax we assumed that sulfur emissions would be reduced in proportion to the overall reduction in the generation of electricity from coal. In practice we would expect the carbon tax to result in idling of the oldest, least efficient, and probably most polluting, coal power plants. The present analysis most likely underestimates in this case the savings in SO<sub>2</sub> emissions that could be realized as an ancillary benefit of a carbon tax.

A carbon tax is expected to promote an increase of demand for natural gas, resulting in an increase in the price of gas and thus an increase in the gas-coal price differential. The reduction in SO<sub>2</sub> emissions would be expected in this case to be less than our present estimate. On the other hand, a decrease in demand for electricity responding to the tax-induced increase in electricity prices would result in a reduction in emissions. The effects are obviously offsetting. A detailed analysis of the consequences is however beyond the scope of the present paper.

**Figure 6** Savings in emissions of SO<sub>2</sub> relative to 2008 as a function of the pre-tax difference in costs for power generation using gas rather than coal (gas-coal) as estimated to result from imposition of a carbon tax on the power sector at three levels (\$5/ton CO<sub>2</sub>, \$10/ton CO<sub>2</sub> and \$20/ton CO<sub>2</sub>). The vertical axes to the left indicate the magnitude of the SO<sub>2</sub> reductions measured in thousands of tons SO<sub>2</sub>. The scales to the right present these data in terms of percentage reductions relative to 2009 for each region.

## 5. Discussion

The present paper focused on analysis of the changes in emissions of SO<sub>2</sub> that took place between 2008 and 2009, a period over which recession in the economy led to a reduction in demand for electricity and when prices for natural gas resulted in significant switching of fuel use in the power sector from coal to gas. We have applied the LMDI methodology also to the more extended time period from 1995 to 2010. Results from this analysis are presented in Figure S6 of SI. It suggests that the trend in emissions of SO<sub>2</sub> over this period closely followed trends in SO<sub>2</sub> emission intensities. Relative to 1995, SO<sub>2</sub> emission intensities decreased by 16.8% in 2000, by 31.7% in 2005 and by 66.8% in 2010, contributing to net decreases in emissions of 2.93% in 2000, 15.8% in 2005 and 56.1% in 2010.

The major driver for the decrease in emission intensities is the Acid Rain Program (ARP) established under Title IV of the CAA Amendments of 1990 (27, 28). The key mechanism for the implementation of the ARP involved the introduction of a cap and trade system to limit emissions of SO<sub>2</sub> emissions. The cap-and-trade system, initiated in 1995, was expanded in 2000 to include all sources, coal, oil and gas fired generating units, with capacities greater than 25 MW. Five years later, in 2005, the US EPA issued the Clean Air Interstate Rule (CAIR) with targets to reduce emissions of SO<sub>2</sub> and nitrogen oxides (NO<sub>x</sub>) from the 28 eastern states and the District of Columbia by 70% percent in 2015. The CAIR is expected to be replaced by an even tighter the Cross-State Air Pollution Rule (CSAPR) in the near future, requiring reductions in emissions of SO<sub>2</sub> of 50% in 2012 and further reductions of 74% in 2014 (29, 30, 31). As a consequence, the decrease of SO<sub>2</sub> emissions was accelerated among the three

time intervals of 1995-2000, 2000-2005 and 2005-2010.

The results in Figure S6 indicate that the regulations promulgated by the US EPA played an important role in triggering the 67% decrease in emission intensity inferred to have taken place between 1995 and 2010 (28). The suggestion in this paper is that the recent decrease in prices for natural gas relative to coal is introducing a new consideration into this dynamics. The decrease is prompting replacement of older, less efficient coal-fired plants by newer, more efficient gas combined cycle plants. The overall increase in removal of sulfur from the coal sector in 2009 reflected in part elimination of the older plants which generally did not incorporate technology for removal of sulfur. If gas prices remain low in the future, we may anticipate that this trend will continue with mothballing of increasing numbers of the more inefficient coal plants, with future increase in the overall efficiency for removal of sulfur from the coal segment of the power generation system. If on the other hand, gas prices recover, the power industry will be compelled to make further, expensive, investments to reduce overall emissions from the remaining coal-fired component of the power sector.

## **Description of SI**

The uncertainties associated with the LMDI approaches are briefly addressed in Figure S1 and related discussion. Figure S2 summarizes the results of analyzing the changes from 2009 to 2010, when the gas prices increased slightly. A sensitivity analysis of the variables in the second-level LMDI is

summarized in Figure S3 and related discussion. The percentages of total electricity generation using coal in the US in 2008 and 2009 are presented in Figure S4 as a function of the ages of the generating plants. In Figure S5, the percentages of coal consumed in US electric power generation in 2008 and 2009 by sulfur content are illustrated for four categories of coal. Results of applying the LDMI methodology to a more extended time period, from 1995 to 2000, are presented in Figure S6. Tables S1 and S2 summarize the data used for the first-level and second-level LMDI analyses, and Table S3 summarizes the immediate effect of carbon taxes in reducing SO<sub>2</sub> emissions for the nine census regions and for the contiguous US as a whole.
